L'accompagnement des chômeurs diminue-t-il la durée du chômage et la récurrence ?¹

Marc Gurgand, Bruno Crépon, Muriel Dejemppe

Résumé

Cet article a pour objet d'évaluer les effets du suivi individualisé mis en place par l'ANPE pour environ 20 % des chômeurs à partir de juillet 2001 (plan d'aide au retour à l'emploi-Pare). À partir de méthodes statistiques exploitant les durées et d'une information très riche, nous pouvons identifier les effets de quatre prestations aussi bien en termes de sortie du chômage vers l'emploi et que de durée passée dans l'emploi après une période de chômage. Nous observons ainsi des effets positifs significatifs dans les deux cas, mais l'impact sur la récurrence est plus fort que sur la vitesse de sortie du chômage. Le programme fait en particulier passer l'incidence de la récurrence, au bout d'un an en emploi, de 33 à 26 %. Les effets sont également plus importants pour les personnes qui ne reçoivent pas d'allocation-chômage. Nous insistons sur le fait qu'il est important d'analyser simultanément la durée de chômage et sa récurrence lorsque l'on évalue les politiques du marché du travail.

Mots-clefs : emploi, chômage, demandeur d'emploi, allocation-chômage, prestations, politique du marché du travail.

¹ La version française du rapport est disponible auprès de l'ANPE sous le titre *Évaluation d'impact du PAP/ND. Effets des prestations sur les sorties du chômage et la récurrence.*

Counseling the unemployed: does it lower unemployment duration and recurrence?*

Bruno Crépon[†], Muriel Dejemeppe[‡] and Marc Gurgand[§]

March 21, 2005

Abstract

This article evaluates the effects of the intensive counseling schemes that are provided to about 20% of the unemployed in France, since the 2001 unemployment policy reform (PARE). Using duration models and a very rich data set, we can identify heterogenous and time-dependent causal effects of the four main schemes, both on transitions from unemployment to employment and on time spent out of unemployment once a job is found. We find significant favorable effects on both outcomes, but the impact on unemployment recurrence is much stronger than on unemployment duration, which can be predicted by search theory. In particular, the program shifts the incidence of recurrence, one year after employment, from 33 to 26%. Effects are also larger for people that do not receive unemployment benefits. We emphasize that it is important to analyze simultaneously unemployment duration and recurrence when evaluating labor market policies.

*This paper is part of a research program founded by ANPE (Agence nationale pour l'emploi). We are very grateful to Julie Micheau, Fabien Couprie and Laurent Josso from ANPE for providing the data and for numerous discussions. 1 Introduction

Among active labor market policies that are believed to have some impact on labor market transitions, increasing attention has been devoted to counseling and job-search assistance, combined with monitoring of the unemployed and sanctions. Many reforms involving some or all of these instruments have been implemented in OECD countries during the 1980s and 1990s (Martin and Grubb, 2001), and the 2001 French reform that we analyze here follows this line. Declining unemployment benefit has long been considered an efficient incentive to search. But monitoring can be proved socially preferable when agents are risk averse, in spite of implementation costs and imperfect observability of search effort (Boone et al., 2001). Moreover, recent theoretical contributions have explored the beneficial effects of unemployment benefits (e.g., Acemoglu and Shimer, 1999, Marimon and Zilibotti, 1999, Acemoglu, 2001). This weakens the case for benefit based incentives and may explain interest for more direct forms of intervention.

In the empirical literature, there is some consensus on the effect of these policies on the duration of unemployment. Compelling evidence that reemployment services are efficient in reducing beneficiaries unemployment duration is available for instance in the US (Meyer, 1995, Black et al., 2003) and the United Kingdom (Dolton and O'Neill, 1996, 2002, Blundell et al., 2004). In the Netherlands, however, Gorter and Kalb (1996) find rather limited impact of a monitoring and counseling program, while van den Berg and van der Klaauw (2003) find none. In view of the literature, though, they argue that job-search support measures do increase the transition rate to work, when they are sufficiently intensive. In addition, counseling should have a positive impact, whereas monitoring may induce the unemployed to search through a less efficient channel. The relative magnitudes of the two components remains an open question because most of the programs that have been evaluated combine job-search assistance and increased monitoring. In this paper, we concentrate on the specific effects of counseling and job-assistance schemes, in isolation from monitoring and sanctions.

Evaluating the effect of these policies on unemployment duration is not sufficient however, because any impact on unemployment rates or employment levels involves both unemployment *and* employment durations. It could be tempting for the public employment service, or any provider, to send workers to short-term or low paid jobs that are quite available, but do not last. This would certainly increase transitions to work. But improving the quality of job matching could be even more desirable. As a matter of facts, counseling schemes often have an explicit matching objective. It is therefore necessary to evaluate the two outcomes altogether. The major point of this paper is that results can be misleading when this is neglected.

Based on a simple search model, we illustrate that job-search assistance is likely to have ambiguous effects on transitions to work, but always increase the reservation wage. If higher paid jobs are less often destroyed, for instance because they are more productive, then counseling should have more systematic (and maybe stronger) effects on unemployment recurrence than on unemployment duration. However, most empirical studies do not attempt to evaluate whether counseling increases job duration, although

this question has been largely investigated for training and employment subsidies (see e.g. Bonnal *et al.*, 1997, Gritz, 1993). Blundell *et al.* (2004) present estimation results which suggest that the New Deal for young people in UK increases by 4.5% points the probability to find a job *lasting at least 13 weeks* (the outcome variable), but the duration of employment is not formally analysed. Dolton and O’Neill (2002) find no effect of the Restart experiment on employment duration, but the program has an important monitoring component which can induce people to accept lower quality jobs.

We consider the major reform of French unemployment policies implemented in July 2001. This *Plan d’Aide au Retour à l’Emploi* (PARE), introduced two main changes. On the one hand, the degressivity of unemployment benefits was suppressed. On the other hand, the public unemployment agency revised its support policy towards unemployed persons. Although some individual assistance was present before that date, mostly in favour of the long-term unemployed, individual follow-up became general and more frequent overall, and significantly larger amounts of job-search assistance services are now provided. The French reform departs from most of the foreign experiences in that very intensive schemes are attributed to a rather modest share of the unemployed (less than 20%), at a high cost (600 million euros a year). More importantly, limited actual monitoring is taking place. A meeting is now compulsory for all newly registered unemployed and recurs at least every 6 months. However, it is not used to control the search activities of the unemployed workers, but mostly serves to decide on their allocation to the job-search assistance programs.

In this study, we measure the effectiveness of the four main counseling schemes proposed by the PAP program in raising the transition rate from unemployment to work and lowering recurrence into unemployment. In some countries, controlled experiments are available. In the present context, neither such an experiment nor a quasi-experimental design is available, because the reform applies uniformly to all unemployed. In a comparable situation, Gerfin and Lechner (2002) or Sianesi (2004) have evaluated several training and subsidized jobs programs simultaneously, using matching methods with rich data bases. However, they have to assume selection on observables. Still, semi-parametric identification of causal parameters in the presence of selectivity on unobservables is possible, relying on the timing of events and the proportional hazard specification (Abbring and van den Berg, 2003). This strategy has been successfully implemented in a set of recent papers (Abbring *et al.*, 2000, Lalive *et al.*, 2002a, 2002b, van den Berg *et al.*, 2000, van den Berg *et al.*, 2004 - see also Bonnal *et al.*, 1997, for an early model in that vein). In this paper, we exploit an exceptional administrative database, set up by the French unemployment agency, that contains data on about 400,000 individual unemployment spells and very detailed information on services actually received, since implementation of the reform until June 2004. The size of the data allows flexible estimation of the impact of the four main schemes of the program, including heterogeneous and time dependent effects. Because sampling is on individuals, we can observe both unemployment duration and recurrence. We find that schemes effects on recurrence are strong and systematic and that all schemes also increase unemployment-employment transitions. Effects are heterogeneous with respect to several characteristics, especially

unemployment insurance benefit. Because only a limited fraction of the unemployed receive treatment, the program increases the proportion that has found a job after one year by less than one percentage point. But it decreases the incidence of recurrence one year after a job is found by more than 6 percentage points. Therefore, if unemployment duration alone was considered, treatment effects would be strongly underestimated.

The plan of the paper is as follows. The next section presents the 2001 reform of the French unemployment policy. Section 3 illustrates the theoretical analysis of counseling within a standard search model. Section 4 describes the data. Section 5 presents the empirical method, and estimation results are discussed in Sections 6 and 7. Section 8 concludes.

2 The 2001 unemployment policy reform in France

The reform introduced in France in July 2001 was originally influenced by foreign experiences but it ended up with quite distinctive features (Freyssinet, 2002). In the original agreement between employer and (some of) employee unions, the degressivity of the unemployment benefit was suppressed in exchange for increased monitoring based on frequent interviews and stronger sanctions, along with extended provision of job-search assistance schemes. This was in the spirit of recent reforms worldwide. However, the government disagreed with the monitoring section of the project. Eventually, sanctions and the definition of acceptable jobs remained based on already existing legal requirements, which are far less compelling than several foreign experiences. In addition, the public unemployment agency (ANPE), that is distinct from the institution providing benefits (UNEDIC), remained in charge of monitoring and counseling for all types of unemployed. As noted by Freyssinet (2002), UNEDIC did not obtain new power with respect to sanctions.

The reform thus consists mainly of two distinct elements: an more generous benefit system overall (for entitled unemployed) and significantly stronger counseling services offered to the unemployed (whether insured or not), labelled the PAP program (*Projet d'action personnalis e*). Regarding the latter, there are two main changes. First, it was not unusual that an unemployed person would never meet the public unemployment agency caseworkers. A meeting (typically 30 minutes long) is now compulsory for all newly registered unemployed and recurs at least every 6 months. This is a low frequency, but not so far from international practice (Martin and Grubb, 2001). Depending on the person's profile, the caseworker can schedule follow-up interviews between two compulsory meetings, and interviews can be requested at any moment by the unemployed workers themselves.

Second, counseling services that existed before the reform are significantly extended, at the cost of increased budget. Some are provided directly by ANPE, others are subcontracted. Before the reform, these schemes were open only to the long-term (more than a year) unemployed. Training and employment subsidies are also in the range of measures proposed to the individuals, but they are not considered in this paper.

During the first compulsory meeting, the unemployed person and the caseworker

come together to an agreement about the degree of assistance that the person should receive. This agreement is based on the person's evaluation of his/her degree of autonomy in job-search and the caseworker's evaluation of his/her capabilities of finding rapidly a job. The interview concludes with the signing of the PAP contract which determines the degree of assistance and the types of services the person *should* receive. In the first interview, most of the unemployed workers are regarded as self-sufficient in their job search. In this or subsequent interviews, the individuals who are considered to need assistance can be offered a scheme, depending on the availability of slots.

We are interested in 4 categories of schemes that group several variants of each type of service¹: two are skill assessments and two are search assistance.

- The basic *Skill assessment* ("Evaluation") lasts typically 1 day. The provider helps the individual assess his professional skills, based on testing and simulated work environment.
- Another skill assessment, that we label *Project assessment* ("Bilan de compétences approfondi"), is aimed at individuals with a professional experience who have difficulties finding a job corresponding to their skills. It lasts 20 hours on average, over a maximum period of 42 days. A personal adviser helps the individual analyse her past experience, identify her skills and match them with a new employment project compatible with the state of the labor market.
- *Job-search support* ("Objectif emploi") is aimed at individuals having a well-defined employment project, but experiencing difficulties in their job search, with the aim of finding rapidly a ("long-term") job. It lasts up to 3 months. In this intensive scheme, the individual is assigned a personal advisor who helps him define the course of actions, teaches on job-search methods (for instance, résumé writing), provides logistic support, proposes job offers or interviews, contacts directly employers and so on. Some actions can be group-based. The bulk of the effort from ANPE is on this scheme.
- Finally, *Project support* ("Objectif projet") is aimed to individuals who wish or have to change profession, but need time and help to define a new employment project. It also lasts 3 months during which the unemployed person has frequent contacts with a personal adviser. The objective of this scheme is similar to Project assessment but there are important differences. Project support is intended for lower ability workers who have stronger difficulties with the labor market and need regular and lasting follow-up. In some cases a placement in the workplace, lasting up to several days or weeks, is scheduled.

Only 17% of the unemployment spells in our data are associated with participation to at least one of these four programs over the whole period 2001-2004. This relatively low figure results partly from the fact that some spells end very rapidly (nearly 20% of

¹These groups have been defined with the help of the ANPE statistics and research Department and they are homogenous in terms of objectives, targeting and length.

spells end in the first month of unemployment). A large majority of spells with treatment (80%) receive only one treatment. Among this group, job-search support is by far the most frequent measure (44%). Figure 1 describes the (monthly) empirical hazards for transition into the schemes. The chances to enter each scheme are typically below 1% per month, with Job-search support being more often provided. This will prove very important for the identification strategy because, with such a low rate, it is unlikely that treatment can be anticipated by potential beneficiaries. Strong peaks are present and they are related to compulsory interviews on the first, 6th and 12th months, but the entry rate remains positive at all dates and does not decline strongly in the long-run.

Although it benefits a limited number of persons, the burden of this program is significant because of high unit costs. The figures in Table 1 relate to the marginal costs of the services. The compulsory meetings with a caseworker have small unit cost, but they are very numerous. Workshop is a light service that is frequently provided and is not evaluated in this paper (it is aimed at individuals who experience only selective problems with their job-search and lasts 1/2 day each).

Skill assessment has a small weight, whereas Project assessment costs almost 900 euros and takes a large share of the budget, although its access is limited. The unit cost of Job-search and Project support is between 300 and 700 euros and they are more often provided. In 2003, ANPE has spent about 440 million euros on these two support schemes, which is the major share of the budget.

Overall, the schemes that are evaluated in this paper thus amount to 600 million euros, approximately 0.04% of GDP, which is a considerable amount for a program that benefits less than a fifth of the unemployed. This is about 20% of the total cost of public employment services and administration.² It is limited however, compared to the cost of the whole active labor market policy, which amounts to 1.25% of GDP (OECD, 2004).

3 The theoretical analysis of counseling

In order to frame the interpretation of the empirical results, we present the theoretical effects of counseling within a job-search model. We assume that the policy ends up increasing the arrival rate of job offers for the treated individuals. When search effort is endogenous, the effect of treatment on transitions from unemployment to employment is generally ambiguous, both because the reservation wage adjusts upward and because the search effort adjusts downward (van den Berg and van der Klaauw, 2003, Fougère, Pradel and Roger, 2004). To illustrate the basic hints of this class of models, we assume that the treated and the untreated draw wage offers from the same distribution, with cumulative function $F(w)$. To receive job offers at a rate s , the untreated must occur a search cost $c(s)$. When treated, the unemployed receive offers at a rate $(s + \Delta)$ for the

²According OECD, this category includes activities of job placement, counseling and vocational guidance, administrating unemployment benefits, and referring job-seekers to available slots on labour market programs.

same cost $c(s)$.³ Δ is thus the structural treatment parameter. The unemployed start with no treatment and enter treatment at rate λ ; they receive unemployment benefits b at a constant level. We consider a stationary, partial equilibrium model, without on-the-job search.

Since our data allows us to measure the effect of the programs on employment duration, we also take into account the effect of counseling on the duration of the job found at exit from unemployment. In the spirit of endogenous job destruction models (Mortensen and Pissarides, 1994, Pissarides, 2000), we assume that productivity shocks occur over time: jobs are destroyed when the productivity drop makes the match no longer profitable. As a result, high productivity jobs are more protected from destruction and last longer. To keep the model simple, we encompass the distribution of shocks and the bargaining process that relates wages to productivity, into a job destruction rate that depends directly on wage, $q(w)$ with $q'(w) < 0$.⁴

Call V_0 and V_1 the values of unemployment without and with treatment and $V(w)$ the value of employment at wage w . With r the discount rate and s_0 and s_1 the search efforts of the treated and the untreated respectively, the values satisfy:

$$\begin{aligned} rV_0 &= b - c(s_0) + \lambda(V_1 - V_0) + s_0 \int \max(V(w) - V_0, 0) dF(w) \\ rV_1 &= b - c(s_1) + (s_1 + \Delta) \int \max(V(w) - V_1, 0) dF(w) \\ rV(w) &= w + q(w)(V_0 - V(w)) \end{aligned}$$

The reservation wages in each unemployment state, w_1^* and w_0^* , verify $V(w_1^*) = V_1$ and $V(w_0^*) = V_0$ and they are implicitly defined by:

$$w_0^* = b - c(s_0) + \frac{\lambda}{r + q(w_1^*)} (w_1^* - w_0^*) + s_0 H(w_0^*) \quad (1)$$

$$\frac{r + \lambda}{r + q(w_1^*)} (w_1^* - w_0^*) = c(s_0) - c(s_1) + (s_1 + \Delta) H(w_1^*) - s_0 H(w_0^*) \quad (2)$$

where $H(w^*) = \int \max(V(w) - V(w^*), 0) dF(w)$ is the expected surplus from accepting jobs above w^* . First order conditions for search effort follow from these expressions and state that marginal search cost equals marginal search benefit:

$$c'(s_0) = H(w_0^*) \quad (3)$$

$$c'(s_1) = H(w_1^*) \quad (4)$$

Assuming that the cost function is increasing and convex, equations (2), (3) and (4) imply that $w_1^* > w_0^*$ and $s_1 < s_0$ (see Appendix 1). When they benefit from treatment,

³This is similar to having two search channels, with a formal channel accessible to the treated at no cost, as in Fougère, Pradel and Roger (2004).

⁴This is equivalent to assuming that the worker has all bargaining power. If y is the productivity of the job and w^* a reservation wage, a more general determination of the wage is $w = \gamma y + (1 - \gamma)w^*$, where γ is bargaining power. This would formally complicate the model without altering the main insights.

the unemployed have the opportunity to make less personal effort. At the same time, they can be more demanding and have a higher reservation wage, because the instantaneous value of unemployment, $b - c(s_1)$, is higher to them. Thus they have higher wages on average when they get a job. Given that higher paid jobs are more protected from destruction, this implies that jobs found by the treated last longer. Indeed the average transition rate from employment to unemployment for individuals with reservation wage w^* is:

$$\bar{q}(w^*) = \int_{w^*} q(w) \frac{dF(w)}{1 - F(w^*)}$$

with $\bar{q}'(w^*) < 0$. If treatment is effective, we should observe $\bar{q}(w_1^*) < \bar{q}(w_0^*)$.

In contrast, the effect of treatment on transition rates from unemployment to employment is ambiguous. Those rates are:

$$\begin{aligned} h_0 &= s_0 [1 - F(w_0^*)] \\ h_1 &= (s_1 + \Delta) [1 - F(w_1^*)] \end{aligned}$$

There are two reasons why the treated can exit unemployment at a lower rate than the untreated even if $\Delta > 0$. First, whether $(s_1 + \Delta)$ is higher or lower than s_0 generally depends on the curvature of the cost function. Second, even if $(s_1 + \Delta) > s_0$, the treated reservation wage is higher. Van den Berg (1994) provides weak conditions on the wage offer distribution for higher rate of job offer still to result in higher transition rate. But they are not sufficient here because of the presence of the cost of search effort.

The variants of this model developed by van den Berg and van der Klaauw (2003) and Fougère, Pradel and Roger (2004) point to the same type of results: the public employment service, when modelled as improving access to job offers, increases reservation wages, but has ambiguous effects on transitions toward employment. In a loose sense, this could be understood as making better matches, which may take time but might be efficient for the economy. In the French reform, several schemes, that are oriented towards building a project in adequation to the state of the labor market, can be understood in this perspective. Even schemes that aim at rapid access to a job emphasize finding long term positions.

The treatment effect parameters that we estimate empirically for transition from unemployment to employment correspond to h_1/h_0 . For transition back from employment to unemployment, our empirical parameters measure $\bar{q}(w_1^*)/\bar{q}(w_0^*)$. As such, they can provide indirect evidence that $\Delta > 0$, i.e. that the schemes are successful in improving treated access to job offers. One must be careful, however, not to interpret h_0 as the transition rate that would be observed if the policy was not implemented at all. By altering market frictions, the policy does modify the general equilibrium of the labor market, and all outcomes are potentially different with and without the policy, or at different treatment rates λ . Following most of the microeconomic evaluation literature, we do not attempt to build the corresponding general equilibrium counterfactuals. Notice that in the short-run, that is before market tension adjusts in equilibrium, the main impact of the policy could be to improve treated outcome at the cost of the untreated, the so-called

"displacement" effect⁵. In the long-run, this must no longer be the sole effect, because stationary levels of unemployment and vacancies respond to the policy.

4 Data and descriptive analysis

The empirical analysis is based on longitudinal data extracted from ANPE records. We use a 1/12 nationally representative sample of all unemployed persons⁶ and we sample all inflow spells between July 2001 and September 2003 but retain only the first spell observed on this period per individual, so as to avoid correlation of unobservables over consecutive spells. Data end in June 2004 and unemployment spells are arbitrarily truncated at 900 days because information becomes very poor after that duration. The data contain a large number of individual characteristics and unemployment history can be traced because individual data is available back to 1993. As emphasized by Heckman et al. (1997), controlling for individual labor market history is of central importance. We retain the following characteristics: gender, nationality, children, marital status, educational level, age, region of residence, reason of entry into unemployment, unemployment history (cumulative unemployment duration since July 1993 and since July 1999), unemployment recurrence (number of spells since July 1999), welfare transfer (RMI) and type of unemployment benefit eligibility.⁷

Entry into and exit from unemployment are recorded on a daily basis, so that we model duration in continuous time. In this data, unemployment differs from the ILO conventional notion, in the sense that people are recorded as job seekers as long as they report so to ANPE on a monthly filled form, even if they have held occasional or short-term jobs, which they have to declare. Some unemployed are classified as "not immediately available" because they suffer from health problems or cannot immediately drop their current occupation to take a job: the corresponding spells are not kept in the sample, as well as that of the handicapped. We also truncate spells when the unemployed reaches 55.

Transitions may occur towards other destinations than employment but they will be treated as censoring, which implies that they depend upon a disjoint subset of parameters. Although undesirable in some instances, this hypothesis maintains a tractable number of parameters to be estimated. Other destinations include training, illness, inactivity and, most importantly, subsidized public employment. In addition, some unemployed do not send their monthly form at some point so that they are known to exit

⁵Davidson and Woodbury (1993) find some displacement effects of a bonus program in equilibrium. Lise, Seitz and Smith (2003) make a strong case that labor market equilibrium analysis is important to the evaluation of the small scale Self Sufficiency Project bonus experiment. However, displacement may be less important for counseling, as opposed to bonus programs, because it should improve the matching of workers and jobs (Meyer, 1995). Indeed, Blundell et al. (2004) find little equilibrium and displacement effect of a counseling program.

⁶The sample consists of all individuals born on March of an even year or October of an odd year. This sample, named "Fichier historique statistique" is updated routinely by ANPE.

⁷In France, the period of entitlement to unemployment benefit is conditional on the length of the last employment spell and on age. The type of UB scheme refers to the length of the entitlement period. The data does not include any information about the amount of unemployment benefit paid to the individual.

but the destination is unobserved. As it would be incorrect to treat them as censored, we have dropped these observations: overall we are left with two third of the initial spells.⁸

ANPE also provided data on the services that benefitted each unemployed worker, with a date for the effective beginning of the scheme. This has been matched with the data on unemployment spells. As reported in Table 2, the sample that is used in estimation contains 390,945 spells, among which 56,784 receive some treatment. Less than half the transitions is toward employment: as a result, the sample that provides information on recurrence is much smaller and the number of treatments is more limited (15,419). We will see below that this puts a limit to specification flexibility in this part of the analysis.

The transitions into the schemes have already been described in Section 2. Table 3 indicates that assignment is certainly not random. Column 1 gives some statistics on the characteristics of individuals who receive no treatment while columns 2 to 5 contain the same information for individuals who have received treatment. Women receive a treatment more often, especially of the project type, probably because their attachment to the labor market is weaker. Education has varying effects: those who benefit Projet assessment are more educated, whereas Skill assessment and Project support are more targetted to intermediary levels. Generally, schemes are less often provided to younger individuals. Being on Welfare has some positive effect as well as receiving unemployment benefit. Finally, having experienced other unemployment spells (since July 1999) increases the likelihood to receive a treatment. This general picture is robust to inclusion of these and additional variables into entirely specified duration models (see Table 5).

When a transition from unemployment to employment takes place, we define an “employment duration” as the time until the individual is back to reported unemployment. Because sampling is based on individuals and not spells, we are certain to observe the individual again in that case. Strictly speaking, the person may not have been in employment all the time, so that it is proper to consider that we measure more exactly *recurrence*. With respect to the explicit objectives of ANPE schemes, this is an important dimension.

Figure 2 displays the empirical hazard rates of the transitions to employment and unemployment. As usual, the unemployment-employment transition exhibits a decreasing pattern with a small increase at one year that may be due to specific employment policies, including those considered here. The same pattern is found for the employment-unemployment transition, with peaks at 3, 6 and 12 months that may be related to standard contract duration.

⁸If we model the main endogenous durations, the likelihood has the form $l(y_E, y_A, y_T|x, u)$, where y_E stands for the duration until exit to employment, y_A the duration to other exits, y_T the durations to treatment, x and u the observed and unobserved characteristics. Then our estimation procedure will be consistent with respect to unknown exits as long as this information is missing at random and the distribution of unobserved heterogeneity is the same for known and unknown exits. This means that if R is a binary variable for known exit, we have both: $l(y_E, y_A, y_T|x, u, R) = l(y_E, y_A, y_T|x, u)$ and $f(u|x, R) = f(u|x)$.

5 Measuring the causal effect of counseling in a duration model framework

Assignment to treatments is likely non-random and is based on the caseworker decision and the unemployed agreement. Both depend on observed and unobserved (to the econometrician) characteristics. In a duration framework, it is possible to identify separately the causal effect of treatment on subsequent duration and the distribution of unobserved characteristics, although both contribute to observed correlations between durations. Abbring and van den Berg (2003) provide identification conditions for the mixed proportional hazards model, based on earlier literature (Elbers and Ridder, 1982, Heckman and Honoré, 1989, Honoré, 1993). Identification is non-parametric, in the sense that no functional form must be assumed for the baseline hazards or the multivariate distribution of unobserved heterogeneity. Moreover, it does not require exclusion restrictions. Abbring and van den Berg show that the elapsed duration until treatment contains useful information to disentangle the causal effect from the effect induced by selection on unobservables. The competing hazards model until entry in a treatment or exit to employment - whichever occurs first - identifies the joint distribution of unobservables. The remaining duration identifies the causal effect of the treatment. The exact timing of events is important because the causal effect is revealed by the change in the unemployment-employment transition hazard rate that occurs once treatment is received (if treatment is effective). This can be distinguished from unobserved heterogeneity because the latter is assumed constant over a spell. In contrast, if unobserved shocks occurred along the spell and their timing was correlated with that of treatment, identification would fail. Arguably, even if this cannot be excluded, controlling for population heterogeneity still goes a long way towards reducing potential bias.

Identification requires that the durations until treatment vary sufficiently. It implies that we should observe individuals at many dates of entry into treatment. As shown in Figure 1, this condition is fulfilled in our data. Even if peaks take place about compulsory meetings (at 0, 6, 12 months), entry rates to the various treatments remain positive at all durations, because individuals or caseworkers can request interviews more often than the legal requirement. Furthermore, unemployed individuals must not anticipate the exact date at which they will enter into a particular program. Otherwise, the program could have some effect *before* actual participation.⁹ Such an anticipation is very unlikely within the PAP scheme, because the average monthly probability to enter a scheme is almost always well below 1% (see Figure 1), due to rationing. Even, if this is higher for some subpopulations, it is unlikely that it can induce significant bias, because the decision to send an unemployed worker to a program depends greatly on the agent in charge and on the number of slots available. Besides, the time between the prescription of a program and its effective start is very short in principle, preventing anticipation behaviour. For instance, it is explicitly required that the program “Project assessment” should start within the next 7 days after its prescription by the caseworker. Unfortunately, the data

⁹A neat example of anticipation is provided by Black et al. (2002) for the *Worker Profiling and Reemployment Services* system in Kentucky.

lack information to check this more strictly.

In this section, we present the statistical model used to identify the causal effect of treatment on our data. We first present the benchmark model based on Abbring and van den Berg (2003), then extend it to account for unemployment recurrence.

5.1 Benchmark model

The empirical model distinguishes the four treatment schemes presented above. We index them with $P \in \{1, 2, 3, 4\}$. Employment is an absorbing state for the moment. Individuals enter unemployment and may exit to one of the treatments or to employment, whichever occurs first. Because we restrict the sample to spells with at most one treatment, people in one of the treatment may then only exit to employment (before censoring). We model the assignment to treatment as a competing risk model. The causal effect of treatment is defined as a shift in the hazard of the transition toward employment, once treatment has occurred. This effect may depend on observed characteristics of individuals and may vary with elapsed duration since entry into treatment.

Call t_U total unemployment duration and t_P the duration until treatment (for individuals without treatment, $t_U = t_P$); x is a set of observed variables and $v = (v_U, v_1, v_2, v_3, v_4)$ is the vector of unobserved characteristics that govern transition from unemployment to employment and transitions to each of the treatments. The conditional hazard rates for transition to each treatment k as function of time since unemployed are:

$$h_k(t|x, v_k) = \theta_k(t)\psi_k(x)v_k, \quad k \in \{1, 2, 3, 4\}$$

where the functions $\theta_k(\cdot)$ and $\psi_k(\cdot)$ represent respectively the baseline hazard and the effect of observed characteristics on the conditional hazard. The joint distribution of the duration to treatment and the received treatment is:

$$f(t, P|x, v) = \left[\prod_{k=1}^4 h_k(t|x, v_k)^{1(P=k)} \right] \prod_{k=1}^4 S_k(t|x, v_k)$$

where $S_k(t|x, v_k) = \exp\left(-\int_0^t h_k(s|x, v_k)ds\right)$ is a survival function; the probability that no treatment has been received up to a duration t is the product of the survival functions as they are (conditionally) independent.

The hazard rate of transitions from unemployment to employment, conditional on the set of observed and unobserved characteristics, received treatment P and duration t_P until treatment is:

$$h_U(t|t_P, P, x, v_U) = \theta_U(t)\psi_U(x)v_U \prod_{k=1}^4 [\delta_k(t - t_P)\varphi_k(x)]^{1(P=k)}$$

The term within square brackets captures the treatment causal effect. It may shift the hazard rate differently according to individual characteristics ($\varphi_k(\cdot)$) and time since treatment ($\delta_k(\cdot)$). The simplest case is when $\delta_k(t - t_P)\varphi_k(x) = \exp(b_k)$, which we label the constant effect model. The corresponding survival function is $S_U(t|t_P, P, x, v_U) = \exp\left(-\int_0^t h_U(s|t_P, P, x, v_U)ds\right)$.

Because in general unobserved heterogeneity (v_1, v_2, v_3, v_4) may be correlated with v_U , we have to model jointly the durations t_U and t_P as well as P . Let denote $c(U) = 1$ when the unemployment spell is not censored and $c(U) = 0$ when it is. The full density of endogenous observations $L(t_U, t_P, P|x, v)$ can be computed from the conditional and marginal densities $f(t_U|t_P, P, x, v)$ and $f(t_P, P|x, v)$, enabling us to write the contributions to the likelihood, accounting for censored durations, as:

$$L(t_U, t_P, P|x, v) = \left[h_U(t_U|t_P, P, x, v_U) \prod_{k=1}^4 h_k(t_P|x, v_k)^{1(P=k)} \right]^{c(U)} \times S_U(t_U|t_P, P, x, v_U) \prod_{k=1}^4 S_k(t_P|x, v_k)$$

To compute the joint distribution of endogenous variables conditional on the observables only, we have to integrate out the unobserved terms. The likelihood is therefore:

$$L(t_U, t_P, P|x) = \int L(t_U, t_P, P|x, v) dG(v)$$

where $G(v)$ is the mixture distribution. Identification of $\theta_k(\cdot)$, $\psi_k(\cdot)$, $\delta_k(\cdot)$, $\varphi_k(\cdot)$, for $k = 1 \dots 4$, $\theta_U(\cdot)$, $\psi_U(\cdot)$, and $G(\cdot)$ follows from Abbring and van den Berg (2003).

5.2 Introducing employment duration

In our data, individuals enter, exit and sometimes reenter unemployment. We consider as an "employment" spell, a spell that begins with an exit from unemployment to employment. The duration of the spell is known when the individual reenters unemployment, otherwise the spell is treated as censored. Because it is unsure that a job has been held during the whole period, recall that the hazard of the transition from "employment" to unemployment is, strictly speaking, a measure of recurrence.

The hazard rate of employment duration is:

$$h_E(t|P, x, v_E) = \theta_E(t)\psi_E(x)v_E \prod_{k=1}^4 [\gamma_k(x)]^{1(P=k)}$$

The causal effect of treatment k on employment duration is $\gamma_k(x)$, and may depend on covariates x . Other notations are obvious. For individuals that exit from unemployment to employment, the likelihood involves an additional term which is the likelihood of the employment spell:

$$L_E(t_E, |P, x, v_E) = h_E(t|P, x, v_E)^{c(E)} \exp\left(-\int_0^t h_E(s|P, x, v_E) ds\right)$$

where $c(E) = 1$ when the employment spell is not censored and $c(E) = 0$ otherwise. The total conditional likelihood is now:

$$L(t_U, t_P, t_E, P|x, v) = L_E(t_E, |P, x, v_E)^{c(U)} L(t_U, t_P, P|x, v)$$

It must also be integrated over the distribution of unobserved terms, enlarged to $(v_U, v_E, v_1, v_2, v_3, v_4)$. Appendix 3 provides a sketch of the demonstration that this distribution, as well as the additional terms $\theta_E(\cdot)$, $\psi_E(\cdot)$ and $\gamma_k(\cdot)$, are identified, using identification results from successive durations models.

5.3 Specification issues

A joint distribution of unobserved heterogeneity with a completely flexible covariance matrix would be very difficult to estimate in practice, as the number of parameters is very large. We choose to model the distribution as a two-factor loading model, assuming that there are two fundamental unobserved factors V_1 and V_2 that enter every duration. The specification of the unobserved terms is thus:

$$v_k = \exp(\alpha_k^1 V_1 + \alpha_k^2 V_2)$$

Let Γ a 6×2 matrix formed by the coefficients α_k^1, α_k^2 . The log-unobserved terms are therefore $w = \log(v) = \Gamma V$, with $V = (V_1, V_2)$. The covariance matrix of w is:

$$\text{Var}(w) = \Gamma \text{Var}(V) \Gamma'$$

The two-factor loading specification imposes no constraint on the correlation matrix, but identification requires some normalization. Clearly for any 2×2 orthogonal matrix¹⁰ Q : $\text{Var}(w) = \Gamma \text{Var}(V) \Gamma' = \Gamma Q' Q \text{Var}(QV) Q' Q \Gamma'$. Thus, if Γ and $\text{Var}(V)$ are solutions, then $\Gamma Q'$ and $\text{Var}(QV)$ are also solutions. This problem can be avoided by assuming that the two underlying factors are uncorrelated and by imposing a restriction on Γ , namely $\alpha_k^2 = 0$ for some k . A frequent and natural choice is to model the unobserved factors as a discrete distribution with mass points, following Heckman and Singer (1984), and interpret it as an approximation to a non-parametric distribution. We thus assume that V_1 and V_2 are independent and are both distributed on the support $\{-1, 1\}$ with distinct probabilities. The information contained in $\text{Var}(w)$ is sufficient to identify the 11 parameters in Γ and the two probabilities. Therefore, no additional constraints are required to normalize the means.

All model parameters are in exponential form. In particular, we model the contribution of explanatory variables as:

$$\psi_k(x) = \exp(x\beta_k)$$

The explanatory variables we introduce are of two types. The first type includes variables like gender, age, education, region of residence, nationality, children, marital status. These can reasonably be considered exogenous. The second type of conditioning variables (note it x_p) is based on past labor market history: reason for entry into unemployment, unemployment recurrence, welfare transfer, unemployment benefit track. They are functions of passed values of endogenous variables, which may generate correlation with unobserved heterogeneity. However, this is not an issue here, as the treatment

¹⁰An orthogonal matrix satisfies $QQ' = I$.

parameters are still consistently estimated if we specify unobserved heterogeneity conditional on observed covariates rather than the opposite. Assume that the unobserved terms are in fact $v_k = \exp(x_p \rho_{kp} + \alpha_k^1 V_1 + \alpha_k^2 V_2)$: it is clear that the parameters ρ cannot be disentangled from the parameters β , but this does not affect the consistency of the parameters δ and γ of main interest.¹¹

Flexibility of the baseline hazard is limited by the practical difficulties in estimating it jointly with the unobserved heterogeneity distribution (Baker and Melino, 2000). We adopt a piecewise constant hazard for the duration dependence functions $\theta_k(t)$, of the form:

$$\theta_k(t) = \sum_{l=1}^{l=L} e^{\theta_{kl}} 1(t \in I_l)$$

For unemployment duration, we allow for seven intervals, the first six of them being of equal length of 90 days, i.e. covering the first one and a half year of unemployment: $I_1 = [1, 90]$, $I_2 = [91, 180]$, $I_3 = [181, 270]$, $I_4 = [270, 360]$, $I_5 = [361, 450]$, $I_6 = [451, 540]$, $I_7 = [541, 900[$. For all other durations, we set five intervals, the first four of them lasting 90 days $I_1 = [1, 90]$, $I_2 = [91, 180]$, $I_3 = [181, 270]$, $I_4 = [270, 360]$, $I_5 = [361, 900]$.

Because local maxima are likely, we run optimization a number of times with randomly chosen starting values. The tolerance for the gradient was set to 10^{-6} and we used Gauss optimum library with the BFGS algorithm in order to be able to deal with the very large number of observations and parameters. Analytical gradients were used to speed-up optimization and to avoid imprecision in the Hessian computation. Out of, say, fifteen set of random starting values, most would converge to the same maximum, and a few would converge to another set of parameters showing a lower likelihood. Having also checked the Hessian closely, we are thus confident that the reported estimates are at a global maximum.

6 Estimation results

6.1 Constant effect model

Table 4 and 5 show the estimates of the constant effect model. Table 4 reports the treatment effects and unobserved heterogeneity parameters; it also reports parameters of a model without unobserved heterogeneity. Comparison between the two illustrates that assuming selectivity on the observables, as with matching methods, would be misleading in some instances. Table 5 contains the estimated effects of duration dependence and individual characteristics on the transition rate from unemployment to work, from employment back to unemployment and to each of the counseling scheme.

True duration dependence (Table 5) is graphed in Figures 3 and 4. Figure 3 describes the estimated duration dependence of the hazards into the schemes. As in the empirical

¹¹This is in the spirit of Wooldridge's (2002) treatment of initial condition in a panel setup. He proposes to model the distribution of unobserved heterogeneity conditional on the first observation and use it to derive the density of observations. In contrast to this approach, however, we do not aim to recover all structural parameters.

hazard rates (see Figure 1), we observe peaks related to compulsory interviews at 0, 6 and 12 months. We also notice that the assignment rate to Job-search support is higher for long-term unemployed, whereas it remains roughly constant over the spells for other schemes. Figure 4 displays the estimated duration dependence of the hazard rates of exits to employment and to unemployment. They are flatter than their empirical counterparts (Figure 2). The unemployment-employment transition exhibits a non-monotonic true duration dependence, decreasing slightly over the first 9 months of unemployment then increasing after 12 month and decreasing again. The employment-unemployment transition exhibits a more pronounced U-shape pattern, first increasing over the first 9 months of unemployment and then decreasing. After 12 months of employment, the hazard rate has dropped by 40%. Peaks at 6 and 12 months may be related to standard contract duration.

Heterogeneity parameters are precisely estimated and the distribution of heterogeneity is balanced, with the four types defined by the combination of the values of $(V1, V2)$ representing 40%, 33%, 15% and 12% of the population. The higher loading factor for all processes, but unemployment duration, is for the same heterogeneity component, $V1$: this implies that a significant share of correlations between durations can be attributed to unobserved factors. The effects of covariates are also precisely estimated and they are in line with the descriptive statistics of Table 3. Notice that the cohort effect obviously captures the cycle: cohorts entering at the end of the period have longer unemployment and shorter employment duration.

We now turn to the effects of treatments on the transition rate from unemployment to work. When unobserved heterogeneity is *not* allowed for, Skill assessment and Job-search support have a positive and significant impact on the exit rate towards work (column1, Table 4). A negative but small impact is found for Project assessment, and Skill assessment has no impact. Introducing correlated unobserved heterogeneity changes some of these results (column 2, Table 4). In particular, the effect of the Job-search support program reinforces strongly: the transition rate of individuals attending this scheme increases by about 73% ($\exp(0.55) - 1$) instead of 46% in the model with no unobserved heterogeneity. The causal effect of Skill assessment is more limited (27%). The negative effect of Project support is small (-12%). Generally, in this specification, Project-type schemes have non-significant or negative effects, something that we will be able to interpret below.

Regarding the effects of counseling on transitions from employment back to unemployment, we observe striking differences whether the model allows or not for selection on unobservables. With *no* unobserved heterogeneity, most effects are positive but small (6 to 14%). The picture is completely reversed when allowing for correlated unobserved heterogeneity, implying strong selectivity into treatment. All schemes have strong causal effects, as they decrease recurrence by 49 to 58%.¹² It is important to emphasize that, because subsidized public employment is not considered among the work exits (and is treated among "other destinations"), this result is *not* driven by the relatively long

¹²These effects are not altered when employment duration is allowed to depend on previous unemployment duration.

average length of the subsidized jobs.

The nature of selectivity into the treatments is detailed in Table 6. Because the estimated correlation of unobserved heterogeneity terms is sensitive to included covariates, only total heterogeneity correlation is relevant to economic interpretation. It is computed as $\text{corr}(\psi_i(x)v_i, \psi_j(x)v_j)$, $i, j \in \{U, E, 1, 2, 3, 4\}$ in the population and is displayed on the top panel. All treatments, but Project support, are provided more intensely to individuals who have ex-ante lower unemployment-employment transition rates. Those negative correlations are rather small, however, leading to limited selectivity effect. The higher unobserved contribution is for Job-search support and this is indeed where the causal effect is most affected by selectivity correction in Table 4. Along the same logic, but with much stronger correlations, treatments are provided to individuals who are more at risk of recurrence. This is driven by unobserved heterogeneity: correlation are all above 0.9 because, in the factor loading approximation to the distribution of v , only one factor happens to be significant for v_E .

The direction of selectivity provides insights on program implementation. It can be considered that ANPE caseworkers are effective in selecting individuals who need treatment because they are particularly at risk of unemployment and recurrence, and this is why favorable treatment effects are underestimated when unobserved heterogeneity is not taken into account. This is important, because the caseworkers could be tempted to adopt the opposite strategy, so as to provide the illusion that they are efficient (or the institution is). In the case of recurrence into unemployment, it seems that caseworkers select individuals who have basic characteristics - such as education and age - that make them able to succeed on the labor market (as witnessed by negative correlation of observed heterogeneity), but have specific personal or motivation problems (unobserved to us) that require some intensive help.

6.2 Heterogenous effects model

In Table 7, we allow treatment effects to vary with some selected individual characteristics, with date of entry into unemployment and with time elapsed since treatment (other parameters are close to those in Tables 4 and 5 and they are not shown). Significant effect heterogeneity is only found for the unemployment-employment transition: such detailed estimation is data demanding and it is likely that we have no sufficient employment duration data with treatment for this model (see Table 2). We thus only comment the upper panel of Table 7. The most striking feature is the retention effect: Project assesment and Project support have a negative effect (for the reference person) immediately after treatment has started, as in the constant effect model. But we now allow this effect to change after three months: it becomes positive, with a net effect of 25% and 19% respectively (at the reference individual, pertaining to the early 2002 cohort). This is perfectly coherent with the function of these schemes: they are meant to build up a professional project and a search strategy before intensive search actually takes place. Because they last up to 3 months, retention effect is found during this period. Then, search becomes more efficient for the treated. Interestingly, Job-search support

does not display such a feature, which is in accordance with its purpose, as described in Section 2. Overall, the orders of magnitude of the treatment effects on transitions towards employment are comparable with those found in the UK by Dolton and O’Neill (1996) for the Restart program and by Blundell et al. (2004) for the New Deal (about 20 – 30%).

All schemes are particularly efficient for the treated with some unemployment experience, a category that indeed more often receives the schemes (see Table 5). Assessment schemes are more efficient for the young, probably because new entrants need to find ways to fit their search strategy with the labor demand. However, the young are less often provided these treatments (Table 5). In contrast, Job-search support seems useful to more experienced persons as well as to more educated ones. It is indeed provided to more educated, but also to the youngest group. Perhaps surprisingly, the educated also benefit more from Project support, but they receive it less often. Overall, correlations between treatment propensity and treatment efficiency are negative.¹³ We compute them as $\text{corr}(\psi_k(x), \varphi_k(x))$, $k \in \{1, 2, 3, 4\}$ where $\psi_k(x)$ is the covariate contribution to the hazard rate into treatment and $\varphi_k(x)$ is from Table 7 (excluding month of entry and the incremental effect, so as to concentrate on individual heterogeneity). Correlations are: -0.38 for Skill assessment, -0.42 for Project assessment, -0.15 for Search support and -0.23 for Project support. This implies that, *as far as observed heterogeneity is concerned*, the schemes are not allocated to those who benefit them the most. But unobserved determinants may be present and be more decisive. Furthermore, this can follow from the fact that the schemes are offered to those who need them more, in the sense that their unemployment risk is higher: these persons may not show the highest treatment effects.

Finally, treatment effects vary very strongly according to the date of entry into unemployment: they are lower for those entered at the end of the period (September 2003) than for those entered at reform starting time (July 2001). For instance, the point-estimate effect of Job-search support can switch from 165% to 61% for the reference individual, and that of Project support, from 52% to 6%. This finding can be driven by several factors. The rise in the number of participants since the launch of the program could reduce its beneficial effect if displacement plays a significant role. This could also reflect a maturation effect (see Blundell *et al.*, 2004): the caseworkers are less involved in the project two years after the launch of the program than they initially were. Finally, the effect of counseling schemes can be sensitive to the state of the labour market and decrease in a recession.

All these results are in accordance with the theoretical analysis of Section 3 and with what we know of the nature of the various schemes. The intensive Job-search support has strong effects on both unemployment and employment duration. As could be expected, the effect of the project schemes on unemployment duration is smaller than its effect on employment duration: this is both because the first effect is ambiguous in theory and because the schemes are meant at setting up a search strategy rather than leaving unemployment fast. Finally, the lighter scheme, Skill assessment, has no effect

¹³This is similar to Black et al. (2003).

on unemployment duration, but still has some effect (the smallest one) on employment duration, something that is compatible with theory.

6.3 Stratifying by unemployment benefit

Transition models with and without unemployment benefits are likely to be different, in particular because the shape of benefit affects the baseline duration dependence. Given our sample size, we can stratify the estimation, and gain robustness in that dimension. Treatment effects are reported on Table 8. Regarding the unemployment-employment transition, contrasts are not very strong and individual heterogeneity seems to affect treatment efficiency in the same direction for the two populations. The effect of Skill assessment and Project assessment is stronger for the insured, the effect of Search support is stronger for the uninsured and there is no difference for Project support. In contrast, when recurrence is considered, all treatments have much stronger effects on the population that does not receive unemployment benefit. For them, treatment decreases transition rates toward unemployment by 52% to 87%. The effects are only 19% to 41% for the beneficiaries.

In order to interpret this contrast, consider the simplest possible search model, where arrival rate of job offers is exogenously higher for the treated: $\pi_1 > \pi_0$. Borrowing notations from Section 3, reservation wages are:

$$w_k^* = b + \pi_k \int_{w_k^*} (w - w_k^*) dF(w), \quad k = 0, 1$$

and

$$\begin{aligned} \frac{dw_k^*}{db} &= \frac{1}{1 + \pi_k [1 - F(w_k^*)]} \\ &= \frac{1}{1 + h_k}, \quad k = 0, 1 \end{aligned}$$

where h_k is the hazard rate out of unemployment. Clearly, if the treated have a higher unemployment-employment transition rate, $h_1 > h_0$, which is indeed our empirical observation, we obtain $dw_1^*/db < dw_0^*/db$: higher unemployment benefit reduces the impact of treatment on reservation wages. It follows that the effect of treatment on employment duration should be stronger for the uninsured. Intuitively, the untreated insured initially have higher reservation wages than their uninsured counterparts: the scope for increasing reservation wage with treatment is therefore more limited. In Appendix 2, we show that this result holds in the more complete model of Section 3, under the sufficient condition that $V''(w) \geq 0$ (in the above simple model we have $V''(w) = 0$). Naturally, the differential effects can also be due to unobserved heterogeneity that is probably distributed differently in the two populations. In contrast, because insured and uninsured are sent to the same workshops, we would not interpret this as reflecting differential effort by the provider.

7 Simulations

The parameters presented above are difficult to interpret directly because the effects on exit rates depend on the baseline value of the hazard function and, when heterogeneous effects are considered, on the distribution of covariates. We consider various measures of the effect of the schemes by way of simulations.

We first compute a set of parameters that are similar to the "treatment on the treated" used in the evaluation literature. Decompose the entire unemployment duration as $t_U = t_P + t_R$ where t_P is duration until a treatment occurs and t_R is residual duration once treatment has been received. We compute the cumulative distribution of t_R on the population that receives a given treatment. We then compute this same cumulative, but with treatment effect set to zero. Our parameter is the difference between the two. Formally, for treatment $k \in \{1 \dots 4\}$:

$$\begin{aligned} UE_k(t) &= \int_x P(t_R < t | P = k, \delta_k(t) = \hat{\delta}_k(t), \varphi_k(x) = \hat{\varphi}_k(x)) \\ &\quad - P(t_R < t | P = k, \delta_k(t) = 0, \varphi_k(x) = 0) dK(x | P = k) \end{aligned}$$

where $K(x | p = k)$ is the empirical distribution of observed covariates in the treated population. Implicit in the condition $P = k$ is the fact that unemployment duration up to treatment (t_P) is not randomly distributed: the parameter is thus evaluated on a selected population both in terms of duration dependence and individual heterogeneity. We define analogously a treatment on the treated parameter for employment duration:

$$\begin{aligned} EU_k(t) &= \int_x P(t_E < t | P = k, \gamma_k(x) = \hat{\gamma}_k(x)) \\ &\quad - P(t_E < t | P = k, \gamma_k(x) = 0) dK(x | P = k) \end{aligned}$$

In order to account for the fact that only a limited share of the unemployed workers receive a treatment, we also measure the effect of the presence of the schemes on the distributions of t_U and t_E in the whole population. This measures the impact of treatments altogether with the intensity of assignment to the treatments. It is simply:

$$\begin{aligned} UE(t) &= \sum_k P(t_k < t, P = k) \int_x P(t_U < t | P = k, \delta_k(t) = \hat{\delta}_k(t), \varphi_k(x) = \hat{\varphi}_k(x)) \\ &\quad - P(t_U < t | P = k, \delta_k(t) = 0, \varphi_k(x) = 0) dK(x | P = k) \end{aligned}$$

because the differential for the untreated ($t_k \geq t$) is 0. Notice that this parameter increases with t both because the share of unemployed that have exited increase with elapsed time but also because the proportion of treated also increases. Accordingly:

$$\begin{aligned} EU(t) &= \sum_k P(t_k < t, P = k) \int_x P(t_E < t | P = k, \gamma_k(x) = \hat{\gamma}_k(x)) \\ &\quad - P(t_E < t | P = k, \gamma_k(x) = 0) dK(x | P = k) \end{aligned}$$

The simplest way to measure all these parameters is to simulate the model. We first draw a random term in the distribution of unobserved heterogeneity for each individual

in the sample. This allows us to compute the quantities $\psi_U(x)v_U, \psi_E(x)v_E, \psi_k(x)v_k, k = 1, \dots, 4$. We then draw four independent values for the durations upon each treatment, i.e. draws in the distribution of t_1 to t_4 conditional on x and v . To this aim, we must take the inverse of the survival function $S_k(x, t) = \exp\left(-\psi_k(x)v_k \int_0^t \theta_k(s) ds\right)$. This is simply the solution of $\int_0^t \theta_k(s) ds = \ln(1 - u_k) / \psi_k(x)v_k$, with u_k a draw in the uniform $[0, 1]$ distribution. The duration to potential treatment is $t_P = \min(t_1, t_2, t_3, t_4)$ and $P = \arg \min(t_1, t_2, t_3, t_4)$. We then draw in the distribution of t_U conditional on x, v_U and t_P . This is performed along the same lines : we draw a random number in the uniform distribution and solve $\int_0^t \theta_U(s, t_P) ds = \ln(1 - u_U) / \psi_U(x)v_U$. The duration dependence is now a function of duration to potential treatment. Once this duration is drawn, we can define the actual duration to treatment, which is censored if exit to employment happens before treatment ($t_U < t_P$). Simulation of the employment duration is performed in a similar way. In the end, every observation is given a sequence of durations, which is not the observed one, but is compatible with estimated joint distributions. This is done again with the effects parameters set to zero. It is important to recall that these simulations provide a synthetic view of the estimated effects, but they are not simulations in the general equilibrium sense.

In order to account for the precision of the estimators, we make these simulations again several hundred times, each time with a different draw into the normal distribution of the entire vector of parameters, using its estimated variance-covariance. The dashed lines in Figures 5 and 6 provide the corresponding 5% and 95% confidence intervals.

Figures 5a to 5d present the parameters $UE_k(t)$ (labelled "exit to employment") and $EU_k(t)$ ("exit to unemployment") for each of the four schemes. Consider first exit to employment. The baseline exit cumulative is not presented in the figures: it is to the order of 30% after 18 months and it reaches about 40% after 900 days. Treatments thus have strong impacts: the share of the unemployed that has exited to a job at some point after treatment increases by up to 5 percentage points for assessment schemes, 10 percentage points for Job-search support and 3 percentage points for Project support, under the effect of treatment. As soon as 5 months after treatment, Job-search support increases by 4 points the proportion that has found a job. The retention effect of the two project schemes is also visible in the figures.

The baseline order of magnitude of recurrence is 30% after 6 months and 70% after 900 days (this rapidly increasing cumulative function is typical of the specific population that benefits more often from treatment). Its shape is strongly affected by the schemes: as compared to the rates that would be observed in the absence of any treatment effect, recurrence is 17 to 25 points lower after 900 days and as much as 7 to 15 percentage points lower after only 6 months.

Figure 6 presents parameters $UE(t)$ and $EU(t)$. They account both for the impact of all four treatments altogether and for treatment intensity. Because less than one fifth of the population receives a schemes at some point, effects are much smaller. They remain significant, however. Due to retention effects and to the fact that schemes are provided progressively, the impact on exit to employment increases very slowly. After a year the gain is only half a percentage point and it reaches one point only after two years. The

impact on exit to unemployment increases faster: the program reduces overall recurrence by 7 points (from 33% to 26%) after only one year.

8 Conclusion

This paper evaluates the causal effects of job search assistance schemes that became central in the public unemployment services since the July 2001 reform in France. Although this is only one dimension of the reform, it is a major innovation in the national context, with substantial budgetary effort, and one that lacks systematic evaluation. The theoretical analysis of this type of intervention predicts that it may decrease unemployment duration but would more surely lower unemployment recurrence. The latter aspect is not routinely considered in the literature, although it has major implications for employment levels in the long run.

The available database makes estimation of those effects possible using identification results that rely only on duration information. Because the data is large, we can exploit all the flexibility that is available within this class of models, making the effects of the treatment depend on elapsed time and observed individual characteristics, even for a large number of potential treatments.

Generally, schemes are provided more often to those that need them the most, in the sense that their risk of long-term unemployment or recurrence is high. All schemes considered are found to have some impact both on unemployment and employment duration. However, the magnitude of the impact is much larger on recurrence than on unemployment duration, which is consistent with our theoretical model. Among the four counseling schemes analysed, the Job-search support program, which receives the largest financial effort from the public employment services, has the strongest effects. In contrast, there is a retention effect on the “project” schemes that is consistent with their design. Heterogeneity of the effects is present in some instances and the efficiency of the schemes decreases with calendar time, to which the economic cycle probably contributes.

Treatment on the treated effects are large, but the overall effect is more limited given that only a small fraction of the unemployed receive treatment. This observation calls for a systematic cost-benefit analysis that cannot be implemented with the current data, because information on wages and the amount of unemployment benefits is lacking. Also, possible general equilibrium effect and displacement effects are not assessed. As a result, one should be cautious before recommending more than a marginal expansion of the policy, based on this evaluation alone.

Appendix 1

First prove that $H(w) > H(w_0^*)$, $\forall w < w_0^*$. We have, from the definition of employment value,

$$V(w) = \frac{w + q(w)V_0}{r + q(w)}$$

Setting $V_0 = V(w_0^*)$ gives $V_0 = w_0^*/r$. Therefore,

$$V(w) = \frac{r}{r + q(w)} \left(\frac{w}{r} \right) + \frac{q(w)}{r + q(w)} \left(\frac{w_0^*}{r} \right) \in \left] \frac{w}{r}, \frac{w_0^*}{r} \right[$$

thus $V(w) < V(w_0^*) = w_0^*/r$, $\forall w < w_0^*$.

Then notice that $V'(w) > 0$ for $w \geq w_0^*$ (below w_0^* , it depends on the shape of function $q(\cdot)$). Therefore:

$$H(w_0^*) = \int \max(V(w) - V(w_0^*), 0) dF(w) = \int_{w_0^*}^{\infty} [V(w) - V(w_0^*)] dF(w)$$

If $w^* < w_0^*$,

$$H(w^*) = \int_0^{w_0^*} \max(V(w) - V(w^*), 0) dF(w) + \int_{w_0^*}^{\infty} [V(w) - V(w^*)] dF(w)$$

and $\int_{w_0^*}^{\infty} [V(w) - V(w^*)] dF(w) > \int_{w_0^*}^{\infty} [V(w) - V(w_0^*)] dF(w)$ because $V(w^*) < V(w_0^*)$. Therefore $H(w^*) > H(w_0^*)$.

Following the literature, we assume that the search cost is positive and convex: $c'(s) > 0$, $c''(s) > 0$. Then, using

$$\begin{aligned} \frac{r + \lambda}{r + q(w_1^*)} (w_1^* - w_0^*) &= c(s_0) - c(s_1) + (s_1 + \Delta)H(w_1^*) - s_0H(w_0^*) \\ &= c(s_0) - s_0c'(s_0) - [c(s_1) - (s_1 + \Delta)c'(s_1)] \end{aligned}$$

we show by contradiction that $w_1^* - w_0^* > 0$. Note that $c(s) - sc'(s)$ is decreasing in s because $c''(s) > 0$. If $w_1^* - w_0^* \leq 0$, $s_1 > s_0$ because $c'(s_0) = H(w_0^*)$, $c'(s_1) = H(w_1^*)$ and $H(w_1^*) > H(w_0^*)$. But then $[c(s_0) - s_0c'(s_0)] - [c(s_1) - (s_1 + \Delta)c'(s_1)] > 0$ and $c(s_0) - s_0c'(s_0) - [c(s_1) - (s_1 + \Delta)c'(s_1)] > 0$. Therefore $w_1^* > w_0^*$ and $s_1 < s_0$.

Appendix 2

Differentiating (2) in text with respect to b yields

$$\begin{aligned} \left\{ \frac{r + \lambda}{r + q(w_1^*)} - (s_1 + \Delta)H'(w_1^*) \right\} \frac{d(w_1^* - w_0^*)}{db} &= \frac{(r + \lambda)(w_1^* - w_0^*)}{(r + q(w_1^*))^2} q'(w_1^*) \frac{dw_1^*}{db} \\ &+ [(s_1 + \Delta)H'(w_1^*) - s_0H'(w_0^*)] \frac{dw_0^*}{db} \end{aligned}$$

The factor in the left-hand side is positive because $H'(w_1^*) = -V'(w_1^*)[1 - F((w_1^*))] < 0$; the first term on the right-hand side is negative because $q'(w_1^*) < 0$. A sufficient condition for $dw_1^*/db < dw_0^*/db$ is therefore $(s_1 + \Delta)H'(w_1^*) < s_0H'(w_0^*)$. If the hazard

rate of the unemployment-employment transition is higher for the treated, $h_1 = (s_1 + \Delta) [1 - F(w_1^*)] > h_0 = s_0 [1 - F(w_0^*)]$, and provided $V''(w) \geq 0$, the following holds:

$$\begin{aligned} (s_1 + \Delta)(-V'(w_1^*)) [1 - F(w_1^*)] &< s_0(-V'(w_1^*)) [1 - F(w_0^*)] \\ (s_1 + \Delta)(-V'(w_1^*)) [1 - F(w_1^*)] &< s_0(-V'(w_0^*)) [1 - F(w_0^*)] \\ (s_1 + \Delta)H'(w_1^*) &< s_0H'(w_0^*) \end{aligned}$$

Therefore, $dw_1^*/db < dw_0^*/db$.

Appendix 3

Consider the trivariate model (t_U, t_P, t_E) for total unemployment duration, duration until (a unique) treatment and employment duration respectively. We observe:

$$\begin{cases} (t_U, t_P, t_E) & \text{if } t_U > t_P \\ (t_U, t_E) & \text{if } t_U \leq t_P \end{cases}$$

Following notations in text, hazard rates are:

$$\begin{aligned} \theta_U(t_U)\psi_U(x)v_U [\delta]^{1(t_U > t_P)} \\ \theta_P(t_P)\psi_P(x)v_P \\ \theta_E(t_E)\psi_E(x)v_E [\gamma(x)]^{1(t_U > t_P)} \end{aligned}$$

We assume identifications conditions as required in Abbring and van den Berg (2003), so that all unemployment and treatment hazard parameters are identified. The densities of interest for the employment part of the model are:

$$\begin{aligned} f(t_U, t_P, t_E, t_U > t_P | x) &= \theta_U(t_U)\theta_P(t_P)\theta_E(t_E)\psi_U(x)\psi_P(x)\psi_E(x)\delta\gamma(x) \\ &\quad \times E_v[v_U v_P v_E \exp(-(Z_U(t_P) + \delta[Z_U(t_U) - Z_U(t_P)]))\psi_U(x)v_U \\ &\quad - Z_P(t_P)\psi_P(x)v_P - Z_E(t_E)\psi_E(x)v_E\gamma(x))] \\ f(t_U, t_E, t_U \leq t_P | x) &= \theta_U(t_U)\theta_E(t_E)\psi_U(x)\psi_E(x) \\ &\quad \times E_v[v_U v_E \exp(-Z_U(t_U)\psi_U(x)v_U \\ &\quad - Z_P(t_U)\psi_P(x)v_P - Z_E(t_E)\psi_E(x)v_E)] \end{aligned}$$

where $E_v[\cdot]$ denotes expectancy with respect to the joint distribution of unobserved heterogeneity (the corresponding integrals are supposed to exist) and $Z_k(\cdot)$ are integrated baseline hazards. We normalize $\psi_E(x_0) = 1$ for some x_0 and $Z_E(t_E^*) = 1$ for some t_E^* . Identification proofs closely follow Honoré (1993).

Identification of $\psi_E(\cdot)$:

Take the limit of $f(t_U, t_E, t_U \leq t_P | x) / f(t_U, t_E, t_U \leq t_P | x_0)$ for $t_U \rightarrow 0$ and $t_E \rightarrow 0$:

$$\lim_{\substack{t_U \rightarrow 0 \\ t_E \rightarrow 0}} \frac{f(t_U, t_E, t_U \leq t_P | x)}{f(t_U, t_E, t_U \leq t_P | x_0)} = \frac{\psi_U(x)\psi_E(x)}{\psi_U(x_0)\psi_E(x_0)}$$

Therefore $\psi_E(x)/\psi_E(x_0)$ is identified, so is $\psi_E(x)$ up to a normalization.

Identification of $\gamma(\cdot)$:

Consider the observable survival function:

$$S(t_U, t_P, t_E, t_U > t_P | x) = E_v[\exp(-(Z_U(t_P) + \delta[Z_U(t_U) - Z_U(t_P)]))\psi_U(x)v_U - Z_P(t_P)\psi_P(x)v_P - Z_E(t_E)\psi_E(x)v_E\gamma(x))]$$

The derivative with respect to t_E is:

$$\begin{aligned} \frac{\partial S(t_U, t_P, t_E, t_U > t_P | x)}{\partial t_E} &= -\theta_E(t_E)\psi_E(x)\gamma(x) \\ &\quad \times E_v[v_E \exp(-(Z_U(t_P) + \delta[Z_U(t_U) - Z_U(t_P)]))\psi_U(x)v_U \\ &\quad - Z_P(t_P)\psi_P(x)v_P - Z_E(t_E)\psi_E(x)v_E\gamma(x)] \end{aligned}$$

Take the limit for $t_U \rightarrow 0$, $t_P \rightarrow 0$ and $t_E \rightarrow 0$:

$$\lim_{\substack{t_U \rightarrow 0 \\ t_E \rightarrow 0}} \frac{\partial S(t_U, t_E, t_U > t_P | x)}{\partial t_E} = -\theta_E(0)\psi_E(x)\gamma(x)$$

Accordingly for the survival on the untreated population:

$$\lim_{\substack{t_U \rightarrow 0 \\ t_E \rightarrow 0}} \frac{\partial S(t_U, t_P, t_E, t_U \leq t_P | x)}{\partial t_E} = -\theta_E(0)\psi_E(x)$$

This identifies $\gamma(x)$ because the rest of the model is already identified.

Identification of G :

Take observations with $t_U > t_P$. The survival function is:

$$S(t_U, t_P, t_E, t_U > t_P | x) = E_v[\exp(-(Z_U(t_P) + \delta[Z_U(t_U) - Z_U(t_P)]))\psi_U(x)v_U - Z_P(t_P)\psi_P(x)v_P - Z_E(t_E)\psi_E(x)v_E\gamma(x))]$$

This function has the form:

$$K(s_U, s_P, s_E) = E_v[\exp(-v_U s_U - v_P s_P - v_E s_E)]$$

As in Honoré (1993), identification of the distribution of unobserved heterogeneity is based on the function K , that is the Laplace transform of G . If K can be identified on an open set of R^3 , then it can be extended on all R and the distribution of G is identified.

To show that K is identified on an open set, we can consider the function

$$\chi : (t_U, t_P, t_E, x) \rightarrow (Z_U(t_P) + \delta[Z_U(t_U) - Z_U(t_P)])\psi_U(x), Z_P(t_P)\psi_P(x), Z_E(t_E)\psi_E(x)\gamma(x)$$

Set $t_E = t_E^*$ so that $Z(t_E^*) = 1$. As Z_U , Z_P , ψ_U , ψ_P , ψ_E , δ and γ are identified, the function χ is identified. Moreover, as Z_U and Z_P are strictly increasing and provided there exists a variable with continuous distribution entering $\psi_E(x)$, then variation in t_U , t_P , and x will span at least an open set in R^3 .

Identification of $Z_E(\cdot)$:

$Z_E(\cdot)$ is identified by letting t_E vary in the survival functions, with x , t_U and t_P fixed.
